

Chapter recap

Last updated February 2024

If you want to use TypeScript in a new project, we recommend using vitejs.dev.

In your command line, run the following command:

```
npm create vite@latest
```

Then enter the project name and choose **Vanilla** and then **TypeScript**.

You will notice that the `tsconfig.json` inside this new project contains the following

`"include": ["src"]`. This instructs the TypeScript compiler which files to process. `src` means it will process all the files starting with `src`, which is equivalent to all the files inside the `src` folder.

You can also fine-tune this by specifying an `exclude` entry.

In the next chapter, we'll learn about TypeScript ESLint. See you there!

Chapter Recap

- TypeScript has a special type called `any` which means the variable can be of any type. This effectively *disables* type-checking for that specific variable.
- You should generally avoid using `any` as it disables TypeScript's type checking.
- A variable with type `any` can have any value and TypeScript will not be able to make a distinction whether it's going to be a string, a number, or any other type.
- `tsconfig.json` is a configuration file that instructs the TypeScript compiler how it should process your code.
- We recommend enabling the `strict` option as it gives you many of the benefits provided by TypeScript.
